Summary
Advanced glycation end-product (AGE) pentosidine has previously been demonstrated in different tissues and body fluids. It was suggested as a novel marker for evaluating the pathologic activity in rheumatoid arthritis (RA). In this study we analyzed the relation between pentosidine and markers of inflammation, cartilage turnover, immune response, and disease status of RA. Using HPLC, we analyzed pentosidine in serum and synovial fluid from 39 patients with RA and in serum from 38 healthy controls. Cartilage oligomeric matrix protein (COMP) and antibodies to CCP (anti-CCP) were measured by ELISA. Clinical disease status was assessed by Disease Activity Score 28 (DAS 28) and functional status by Health Assessment Questionnaire (HAQ). We demonstrated significantly higher serum levels of pentosidine in RA patients in comparison with controls. Pentosidine in serum significantly correlated with pentosidine in synovial fluid. Serum pentosidine levels were associated with erythrocyte sedimentation rate (p < 0.03) but not with CRP, COMP, anti-CCP antibodies, DAS 28, or HAQ. In contrast to previous studies, we could not show any correlation of pentosidine levels with inflammatory status, clinical disease activity, markers of immune response, or cartilage breakdown. However, AGEs can be suggested as important players participating in joint destruction rather than markers of disease activity.

Key words
Pentosidine • Advanced glycation end-product (AGE) • Rheumatoid arthritis • Cartilage oligomeric matrix protein (COMP) • Anti-CCP antibodies

Introduction
Pentosidine represents one of the well-characterized members of advanced glycation end-products (AGEs) that are formed during spontaneous reaction of pentoses with free amino groups such as lysine and arginine. It is apparent that beside non-enzymatic glycation, oxidative stress, and inflammatory processes significantly accelerate the formation of AGEs. Pentosidine has been found in a variety of human tissues where it forms both adducts and intermolecular cross-links, which are suggested to be the link between tissue damage and the aging process (Sell and Monnier 1989). AGEs accumulation is associated with several age-related diseases including diabetes mellitus (Monnier et al. 1992, Dyer et al. 1993), renal failure (Miyata et al. 1996), or
Alzheimer disease (Smith et al. 1994).

The highest accumulation of AGEs was observed in tissues with long-lived proteins such as in articular cartilage collagen (Takahashi et al. 1994, Verzijl et al. 2000). This phenomenon is proposed to be responsible for the modification of both biochemical and mechanical properties of the hyaline cartilage during aging (Verzijl et al. 2003). In addition to articular cartilage (Takahashi et al. 1994), higher accumulation of AGEs has also been detected in synovial tissue (Drinda et al. 2002), serum, urine, and synovial fluid in patients with rheumatoid arthritis (RA) (Takahashi et al. 1997, Miyata et al. 1998, Chen et al. 1998, 1999). RA represents a chronic inflammatory autoimmune disease affecting joints as well as extraarticular tissues. Cartilage destruction and bone erosion, the main phenomena of RA pathology, are induced by hyperplastic synovium containing activated synovial fibroblasts and immune cells (Karouzakis et al. 2006, Stanczyk et al. 2006). These cells can trigger production of reactive oxygen species thereby increasing oxidative stress that is supposed to contribute to the pathogenesis of RA (Hitchon and El-Gabalawy 2004). It represents a vicious cycle contributing to higher levels of pentosidine in joint tissues and body fluids in RA patients as mentioned above. Moreover, higher levels of pentosidine in body fluids of RA patients correlated significantly with inflammatory markers including C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), white blood cell count, and platelet count, as well as with activity of the disease, making pentosidine a potential novel RA biomarker (Takahashi et al. 1997, Miyata et al. 1998, Chen et al. 1998, 1999).

Cartilage oligomeric matrix protein (COMP) is a non-collagenous glycoprotein that is supposed to be a marker of cartilage destruction (Neidhart et al. 1997). Its increased levels in the serum are good prognostic markers for further rapid joint destruction in patients with early RA (Forslind et al. 1992). COMP is decreased in RA patients treated with anti-TNF-α (Crnkić 2003). In recent years, many studies focused on the analysis of anti-cyclic citrullinated peptides (anti-CCP) that have been suggested to be of diagnostic and prognostic benefit for patients with RA (Vencovsky et al. 2003, Raza et al. 2005). Anti-CCP antibodies might become a new diagnostic criterion that can discriminate between RA and non-RA patients in the early onset of the disease.

We have recently shown that higher serum pentosidine levels correlated significantly with marker of cartilage destruction COMP in synovial fluid from patients with knee osteoarthritis (OA) (Šenolt et al. 2005). We therefore explored in the present study the relationship of pentosidine with disease activity status, markers of inflammation, cartilage destruction, and anti-CCP antibodies in patients with established and active RA.

**Methods**

**Patients**

Thirty-nine patients with active RA (32 females and 7 males, mean age 52.8 years), regularly followed at the Institute of Rheumatology in Prague, Czech Republic, were enrolled to this study. Patient’s characteristics are given in Table 1. All patients fulfilled the criteria of the American College of Rheumatology (ACR) for the diagnosis of RA (Arnett et al. 1988). Synovial fluid was collected at the time of knee joint effusion as a part of the therapeutic regimen. Blood samples were withdrawn at the time of synovial fluid aspiration. After collection, serum and synovial fluid samples were stored at −20 °C. The control group, described in our previous study (Šenolt et al. 2005), included 38 healthy volunteers (23 females and 15 males, mean age 58.3 years) without a history of joint disorders who agreed with blood withdrawal. Individuals with diabetes mellitus and/or abnormal serum creatinine or renal disorder were not included in this study. All individuals signed informed consents and the study was approved by the local Ethics Committee.

**Clinical disease activity assessment**

Clinical disease activity of RA patients was assessed by the Disease Activity Score 28 calculated according to the DAS 28 formula with four variables [0.56 √ (number of tender joints) + 0.28 √ (number of swollen joints) + 0.7 Ln (ESR) + 0.014 (patient’s assessment of disease activity)] (Prevoo et al. 1995). The functional status of RA patients was assessed by the Health Assessment Questionnaire (HAQ) (Ramey et al. 1992). All RA patients were treated with a low dose of glucocorticoids and disease modifying drugs (DMARDs) and none of them was treated with biologically drugs.

**High performance liquid chromatography**

As described earlier (Špaček and Adam 2002), pentosidine was measured by the high performance liquid chromatography (HPLC) combined with sensitive
The method developed in our laboratory is based on reversed phase HPLC using Shimadzu HPLC system (model: LC 10ADvp; Kyoto, Japan) operated by CLASS VP software, gradient flow of mobile phase and sensitive fluorescent detection ($\lambda_{\text{excitation/emission}} = 335/385 \text{ nm}$). The separation was performed using compact glass column CGC Separon SGX C18 packed with spherical silica gel particles (with diameter 7 μm) embedded with C18 (octadecyl) group, sized 150x3 mm (Tessek, Prague, Czech Republic); mobile phase (degassed with helium): 0.02 M heptafluorobutyric acid, 0.01 M (NH₄)₂SO₄ and linear gradient was given by a variable concentration of acetonitrile (12.5-25 % ACN within 20 min), column temperature was 40 °C, flow rate 0.5 ml/min and time of HPLC run about 30 min, injection 10 μl. Reproducibility of the HPLC determination itself was 98.8 %.

Pentosidine synthetic standard was prepared in our laboratory by modification of the procedure provided kindly by Prof. V. M. Monnier (Case Western Reserve University, Cleveland, OH, USA). Pentosidine standard was synthesized by direct non-enzymatic reaction of carbohydrates with amino acids using poly-L-lysine (hydrobromide), D-ribose, N-α-acetyl arginine, and DETEPAC (a chelate complex former) (Sell and Monnier 1989). Sample pretreatment included acid hydrolysis (in aliquot of 12 M HCl), purification and preconcentration by solid phase extraction, vacuum evaporation of excessive solvents using SpeedVac (Savant, USA) and reconstitution in the mobile phase prior to injection into HPLC.

**ELISA**

COMP levels were analyzed with a new sandwich ELISA, employing two monoclonal antibodies 17-C10 and 16-F12 that were purified from ascitic fluid by chromatography on a column of immobilized Protein G and concentrated by ultrafiltration. Monoclonal antibody 16-F12 was used as the first (capture) antibody, and biotinylated monoclonal antibody 17-C10 was used as the second (detection) antibody in the assay. The protocol for COMP detection was described earlier (Vilím et al. 2003). Intra- and inter-assay variability was less than 7 % and less than 8 %, respectively.

Antibodies directed to citrullinated peptides (anti-CCP) were detected by commercially available ELISA for anti-CCP2 according to the manufacturer’s protocol (Immunoscan RA, Euro-Diagnostica, Malmoe, Sweden). The results were expressed in U/ml with cut-off for normal levels at 25 IU/ml.

**Statistical analysis**

Values are expressed as means ± S.E.M. The Mann-Whitney U-test was used to evaluate statistical significance of difference between two groups. Linear regression analysis was performed to find the relationship between two variables; statistical significance of the correlation was determined by means of the Spearman coefficient. P<0.05 values were considered statistically significant.

**Results**

**Increased pentosidine levels in patients with rheumatoid arthritis**

Pentosidine levels in serum were significantly higher in RA patients than in control individuals.

![Table 1. Characteristics of patients with rheumatoid arthritis (RA) and control individuals.](image-url)
Pentosidine was significantly higher in the serum than in synovial fluid (155.0 ± 20.9 vs. 85.4 ± 11.3 nmol/l, \( p < 0.001 \)) and the levels in both compartments significantly correlated with each other (\( r = 0.97, p < 0.001 \)) (Fig. 1). When the levels of pentosidine in both serum and synovial fluid in RA patients were compared with the levels measured in patients with osteoarthritis (OA) in our previous study (Šenolt et al. 2005), surprisingly, only an insignificant increase of pentosidine levels in RA compared to OA was observed (155.0 ± 20.9 vs. 132.1 ± 9.2 nmol/l, \( p = 0.87 \) for the serum and 85.4 ± 11.3 vs. 70.7 ± 3.8 nmol/l, \( p = 0.67 \) for synovial fluid).

**Discussion**

In this cross-sectional study we have not confirmed previously demonstrated relationship of higher pentosidine levels with clinical disease activity and markers of inflammation in patients with RA. Additionally, no association was observed between pentosidine levels and markers of cartilage turnover or immune response.

Recently, the accumulation of AGE in articular cartilage has been proposed as a molecular mechanism by which aging may predispose to the development of OA (DeGroot et al. 2004). In addition, higher levels of pentosidine in body fluids were described by several research groups in patients with arthritic complaints. We have previously shown that in patients with knee OA higher levels of pentosidine correlated with a marker of cartilage breakdown COMP in synovial fluid as well as with faster radiological progression of the disease (Pavelka et al. 2004, Šenolt et al. 2005). The association of higher levels of pentosidine with the disease status and activity of RA patients was also demonstrated (Takahashi et al. 1997, Miyata et al. 1998, Chen et al. 1998, 1999).

Previously we found a positive correlation between pentosidine and COMP in synovial fluid in OA patients (Šenolt et al. 2005), and we explored therefore whether our idea – an association between increased oxidative stress and cartilage breakdown – is also relevant to RA. However, we could not confirm this hypothesis since we did not find any correlation between body fluid levels of pentosidine in RA patients and disease activity status assessed by CRP, DAS 28 or HAQ. In the studies that found positive correlations with pentosidine levels (Takahashi et al. 1997, Chen et al. 1998, 1999), clinical...
activity was measured by different disease activity assessments such as the Lansbury index, which may, at least partially, explain the dissimilar findings. In our study, the erythrocyte sedimentation rate represented the only marker of chronic inflammation that correlated with pentosidine serum levels. Levels of pentosidine in the serum are higher than in the synovial fluid. Thereby, we suggest that systemic circulation represents the main source of pentosidine production that is probably the result of chronic duration of the inflammatory disease, but it is not related to the acute inflammatory response or disease activity.

Comparing the serum and synovial fluid pentosidine levels in RA patients with those levels previously reported by our group in OA patients, we found, unlike others (Takahashi et al. 1997, Chen et al. 1998, 1999), that there is only an insignificant increase of body fluid pentosidine in RA patients. Since the mean age of the OA group was significantly higher, an age-related increase of pentosidine might be the reason for this increase in OA patients. Previously, it has been shown that AGE can modify IgG and induce persistent IgM anti-IgG-AGE antibody response and can thus play a role in immune response in RA (Lucey et al. 2000, Newkirk et al. 2003, Hein et al. 2004). The latter authors demonstrated that there is an association between serum pentosidine and pro-inflammatory cytokine IL-6 in patients with RA. Moreover, they found a higher synovial fluid pentosidine in rheumatoid factor positive patients than in those with a negative rheumatoid factor. Consequently, we explored a putative association between pentosidine and anti-CCP antibodies – a specific marker for the diagnosis and prognosis of RA. Despite the fact that anti-CCP positive patients tended to have higher serum levels of pentosidine, the difference between anti-CCP positive and anti-CCP negative patients with respect to pentosidine levels was not significant. According to our results, there is no clear association between pentosidine levels and anti-CCP antibodies as a marker of immune response.

In conclusion, our study does not support the idea that pentosidine represents a valuable marker of disease activity in patients with RA. Moreover, no relationship between pentosidine and markers of cartilage breakdown or immune response could be demonstrated. However, it has been recently shown that advanced glycation end-products can modulate the behavior of synovial fibroblasts and chondrocytes, activate MAP kinase ERK and NF-κB, and to stimulate the production of some MMPs (Loeser et al. 2005, Steenvoorden et al. 2006). Thus, advanced glycation could contribute to the joint destruction during chronic rheumatic diseases in situ, which disclose a new paradigm for future research.
