Summary

Adaptation to continuous normobaric hypoxia (CNH) protects the heart against ischemia/reperfusion injury but much less is known about its potential therapeutic effects. The aim of this study was to find out whether post-infarction exposure to CNH can attenuate the progression of heart failure. Ten-week-old male rats underwent myocardial infarction (MI) or sham operation. MI was induced by 60-min coronary artery occlusion. Seven days post-MI, the rats were randomly assigned to two groups: i) sedentary controls kept at room air and ii) rats exposed to CNH (12% O₂, 3 wks). Echocardiographic examination of the left ventricle (LV) was performed 3 days before surgery and 7, 14 and 28 days post-MI. MI resulted in a gradual increase in LV end-diastolic diameter (LVDₐ) compared to sham-operated animals. Fractional shortening (FS) decreased from 42.8% before MI to 15.1% on day 28 post-MI. CNH significantly attenuated ventricular dilatation without affecting scar area and FS. Our data suggest that prolonged exposure to CNH has certain potential to attenuate the progression of unfavorable changes in ventricular geometry induced by MI in rats.
It has been well established that adaptation to chronic hypoxia confers long-lasting cardioprotection against various manifestations of injury caused by acute ischemia/reperfusion (I/R) insult. Increasing evidence has indicated that ischemia-resistant cardiac phenotype can be induced by both continuous hypoxia (Neckář et al. 2013, Chytilová et al. 2015) and certain regimens of intermittent hypoxia (reviewed in Kolář and Ošťádal 2004). However, much less attention has been paid to potential beneficial effects of chronic hypoxia in secondary prevention of chronic ischemic heart disease and post-infarction heart failure (HF). Del Pilar et al. (2006) demonstrated that intermittent hypobaric hypoxia (IHH) improved myocardial perfusion in patients with severe coronary heart disease. Exposure to repeated brief cycles of hypoxia and normoxia for 4 wks improved cardiac contractile function in a transgenic mouse model of HF (Naghshin et al. 2012). Moreover, therapeutic action of IHH on post-infarcted rat hearts has been reported that manifested as a limitation of scar size and attenuation of both progressive myocardial remodeling and contractile dysfunction. These effects can be related to the increased angiogenesis and reduced apoptotic response in the border zone of infarction (Xu et al. 2011). It is unknown whether similar beneficial effects can be afforded by continuous hypoxia. Therefore, the aim of this study was to find out whether prolonged continuous exposure of rats to hypoxia ameliorates progression of post-infarction HF.

Adult male Wistar rats (10-wk-old, initial body weight 340 - 390 g, Anlab, Czech Republic) were housed in a controlled environment (23°C; 12:12-h light-dark cycle) and given water and a standard chow diet ad libitum. Animals were randomly assigned into 3 groups: i) sham-operated (Sham), ii) rats with myocardial infarction (MI) and iii) rats with MI exposed to continuous normobaric hypoxia (CNH) (MI/CNH). The study was conducted in accordance with the Guide for the Care and Use of Laboratory Animals (National Academy of Science, National Academy Press, Washington D.C.). The experimental protocols were
approved by the Animal Care and Use Committee of the Institute of Physiology of the Czech Academy of Sciences.

Acute I/R insult was performed in anesthetized (sodium pentobarbital, 60 mg kg\(^{-1}\) i.p.) open-chest rats ventilated with room air essentially as described previously (Neckář \textit{et al.} 2002), except for coronary artery occlusion prolonged to 60 min. Sham surgery was performed identically without occlusion. Then all spontaneously breathing animals recovering from anesthesia were housed in separate cages and received analgesia (ibuprofen, 6 mg/day p.o.) for another two days.

Since day 7 post-MI, the rats assigned to CNH were housed for 3 wks in a hypoxic normobaric chamber (12% O\(_2\)) equipped with hypoxic generators (Everest Summit, Hypoxico Inc., NY, USA). A single 30-min reoxygenation period occurred at day 14 for echocardiographic examination.

Echocardiography was performed 3 days before MI and 7, 14 and 28 days post-MI using GE Vingmed System Five (GE Vingmed Ultrasound, Horten, Norway) and FPA 10 MHz probe (GE Vingmed Ultrasound, Horten, Norway). Animals were anesthetized with 2% isoflurane (Forane; Abbott Laboratories, Queenborough, UK) mixed with room air. Echocardiographic data were recorded and analysed in short and long axis of the heart and in 2D-mode and M-mode. Directly measured LV end-diastolic and end-systolic parameters included cavity diameter (LVD\(_d\) and LVD\(_s\)), anterior wall thickness (AWT\(_d\) and AWT\(_s\)) and posterior wall thickness (PWT\(_d\) and PWT\(_s\)). Based on the LV dimension, fractional shortening (FS) was derived as follows: \(\text{FS} \, (\%) = [100 \times (\text{LVD}_d - \text{LVD}_s)/(\text{LVD}_d)]\). Values of heart rate (HR) were averaged from at least 4 heart cycles.

After the last echocardiographic measurement, hearts were excised, washed with Tyrode’s solution, perfusion-fixed and stored in 4% paraformaldehyde for 2 days at 4°C. Hearts were cut perpendicularly to the long axis at the largest circumference, embedded in
paraffin, sectioned (9-μm slices) and stained with Picrosirius Red (Sigma-Aldrich, St. Louis, Missouri, USA). Slices were recorded with Olympus VS 110-S1 microscope (lens magnification 20×; Olympus, Hamburg, Germany) traced with computerized planimetry (OlyVIA 2.4, Olympus; NIS Elements 4.11, Laboratory Imaging, Prague, Czech Republic) and the relative scar area (scar area/LV area) and scar circumference (scar midwall length/LV midwall circumference) were determined (Pfeffer et al. 1979) and expressed in percentage.

Data are presented as means ± S.E.M. Statistical evaluations were done using one-way ANOVA with Newman-Keuls post-hoc test using GraphPad Prism 6 (GraphPad Software, San Diego, CA, USA). Differences were considered significant when $P < 0.05$.

I/R insult led to 56% mortality within 48 h post-MI compared to 100% survival in sham-operated group. Sustained ventricular fibrillation was the main cause of death. Mortality was comparable to earlier reports using similar models of large MI (Pfeffer et al. 1985, Bech et al. 1990) and did not change since day 2 post-MI. Contraction of LV anterior wall ceased after MI, AWT$_d$ and AWT$_s$ decreased by 17.7% and 43.1%, respectively, compared to Sham group at day 7 and did not change significantly till day 28; the exposure to CNH had no effect. No differences in PWT were observed among the groups, except for the 16.1% increase in PWT$_d$ in MI/CNH compared to Sham group (Table 1). As shown in Fig. 1A, LVD$_d$ progressively increased after MI and CNH significantly attenuated this effect: between days 7 and 28, LVD$_d$ grew by 13.7% and 3.9% in MI and MI/CNH groups, respectively. Corresponding changes occurred in LVD$_s$ (Table 1). FS dropped markedly after MI but no beneficial effect of CNH was observed (Fig. 1B). Histological analysis did not reveal any effect of CNH on scar area (21.0 ± 1.1% and 19.8 ± 2.0% in MI and MI/CNH, respectively) and scar circumference (39.4 ± 2.4% and 39.4 ± 3.9% in MI and MI/CNH, respectively) (Fig. 1C).
As adaptation to CNH resulted in lower body weight compared to MI group (Table 1), it can be argued that body growth retardation was responsible for the attenuation of MI-induced LV dilatation (Litwin et al. 1994). However, the relationship between body weight and LVD_d (Fig. 1D) clearly shows that it cannot fully explain the beneficial effect of CNH. Similar attenuation of LV dilatation has been observed in infarced rats exposed to chronic IHH which did not affect body weight (Xu et al. 2011). It also should be noted that the CNH-induced LVD_d lowering compared to MI group was independent of the proportion of scar tissue (Fig. 1E). In contrast to the study of Xu et al. (2011), we did not observe any improvement of FS in infarcted rats adapted to CNH. The reason for this discordance is unknown but differences between models and protocols of IHH and CNH can play a role. In addition, it cannot be excluded that the large extent of MI injury in our study already exceeded the limits of potential effective amelioration of systolic function by chronic hypoxia.

In conclusion, the prolonged exposure of rats to CNH has certain therapeutic potential against the unfavorable changes in ventricular geometry induced by severe MI. Further studies are needed to optimize CNH protocol in order to alleviate the progression of MI-induced heart failure.
