Short title: CLA with rosiglitazone increase atherogenicity in rats
Summary

The cis(c)-9, trans(t)-11 (c9,t11) and t10,c12 isomers of conjugated linoleic acid (CLA) have been reported as agonists of peroxisome proliferator-activated receptor (PPAR) and beneficial in lipidemia and glycaemia. However, it is unclear whether CLA isomers enhance or antagonize effects of conventional drugs targeting PPAR. Male Sprague-Dawley rats were fed high fat diet (HFD) for 8 weeks and treated without or with CLA, rosiglitazone or both for 4 weeks. Oral glucose tolerance and surrogate markers of insulin resistance were not significantly different for all treatments compared to untreated normal diet (ND) or HFD group, except lipoprotein levels. The combination of CLA and rosiglitazone had suppressed levels of low and high density lipoproteins (46% and 25%, respectively), compared to HFD-alone. Conversely, the atherogenic co-efficient of the animals received HFD or HFD+rosiglitazone+CLA was 2-folds higher than ND, HFD+rosiglitazone or HFD+CLA. Of note, isolated aortic rings from the combined CLA and rosiglitazone treated animals were less sensitive to isoprenaline-induced relaxation among endothelium-denuded aortas with a decreased efficacy and potency (Rmax=53±4.7%; pEC50=6±0.2) compared to endothelium-intact aortas (Rmax=100±9.9%; pEC50=7±0.2). Our findings illustrate that the combination of CLA and rosiglitazone precede the atherogenic state with impaired endothelium-independent vasodilatation before the onset of HFD-induced insulin resistance.

Keywords

PPAR agonist; high fat diet; high density lipoprotein; rosiglitazone; atherogenic
**Introduction**

Type 2 diabetes mellitus (T2DM) is one of the major global health burdens and have reached worldwide epidemic. T2DM is accompanied by major hallmarks such as atherogenic dyslipidemia and endothelial dysfunction (Mooradian 2009, Bakker et al. 2009). Together, these hallmarks predispose T2DM patients to cardiovascular diseases. The current options available for treatment and management of T2DM are relatively limited, having problems with non-negligible side effects, and/or often require multiple combinations of drugs that mostly potentiate the adverse effects.

Thiazolidinediones (TZD) or glitazones are oral anti-hyperglycemic drugs commonly referred as “insulin sensitizers”. The use of these glitazones, including rosiglitazone, have been cautioned for increased risk of cardiovascular diseases in T2DM patients (Hiatt et al. 2013, Nissen and Wolski 2007, Nissen and Wolski 2010). This prompts the search for alternative drugs with a better clinical safety profile or suitable supplements to combat the adverse effects of TZD without altering its insulin sensitizing potential.

Conjugated linoleic acids (CLA) refer to a group of positional and geometric isomers of octadecadienoate (C18:2) with conjugated double bonds. Specifically two isomers of CLA, cis-9, trans-11 (c9,t11) and trans-10, cis-12 (t10,c12) isomers exist in abundance in dairy products and ruminant meats (Pariza et al. 1999) and garnered immense interest for their biological activity (Dilzer and Park 2012, Mohankumar et al. 2011, Shokryzadan et al. 2015, Taylor and Zahradka 2004). Of note, unlike TZDs, dietary supplementation of CLA has been shown to promote weight loss in obese animals and weight gain in lean animals, prevent cardiac hypertrophy and blood pressure elevation in spontaneously hypertensive rats (Alibin et al. 2008, DeClercq et al. 2012), and decrease LDL cholesterol in obese insulin-resistant rats and healthy human subjects (Derakhshande-Rishehri et al. 2015, Noone et al. 2002,
These distinct properties of CLA compared to TZDs suggest that there is a possibility that CLA may be used as an alternative supplement or substitute to combat the adverse effects of TZD.

In regards, a previous study conducted in mice fed a high fat diet demonstrated that supplementation with CLA prevented weight gain in rosiglitazone-treated mice without affecting the insulin sensitizing effects of rosiglitazone (Liu et al. 2007). However, it is not clear whether or not co-administration of CLA and TZD alter lipoproteins level and vascular functions. The present study therefore examined the effects of CLA isomers and rosiglitazone either alone or in combination on surrogate markers of insulin resistance, including lipoproteins, and on vascular contractility in rats fed high fat diet.

**Methods**

**Chemicals**

Rosiglitazone was purchased from LKT Laboratories (R5773), USA. Conjugated linoleic acid (1:1 ratio of c9,t11 and t10,c12) was purchased from Nu Chek Prep (UC-59-AX), USA. (R)-(−)-Phenylephrine hydrochloride and isoproterenol hydrochloride (isoprenaline) were purchased from Tocris Bioscience, UK.

**Animals and diet**

Thirty male Sprague-Dawley (SD) rats (6-weeks old) were received (Monash University Malaysia Campus, Malaysia) and acclimatized with normal rodent chow diet (Altromin, 1324, Germany) for two weeks. We selectively used male rats as they are known to be more susceptible to metabolic disorder than female rats and to avoid the estrous cycle mediated interference on metabolic parameters in female rats. The experimental protocol was approved
by the Faculty of Medicine Institutional Animal Care and Use Committee, University of Malaya (Approval number: 2014-03-05/PHAR/R/DDM) and the Animal Welfare and Ethical Review Body, University of Nottingham. Food and water were provided *ad libitum*.

The rats were divided into groups fed with normal diet (ND; 4.10% total energy from fat; 6 rats) and high fat diet (24 rats; 60% total energy from fat; Research Diets, D12492, USA). After completion of 8 weeks of HFD feeding, rats were divided into the following groups and treated for 4 weeks: HFD control (HFD), HFD treated with rosiglitazone (HFD+RGZ), HFD treated with CLA (HFD+CLA) and HFD treated with rosiglitazone and CLA (HFD+RGZ+CLA). CLA was dissolved in 5% w/w fat free milk and administered at 0.2 g per animal per day by oral gavage. The dose of CLA is based on the human consumption equivalent, which amounts to 1 – 2% of dietary weight per day. On average, a rat consumes 20 grams of food per day. With this assumption, we calculate that each rat should be given 0.2 grams of CLA per day. The control rats received only 5% w/w fat free milk. Rosiglitazone was administered daily by intraperitoneal injection at 2 mg/kg body weight and control rats received only saline injection. The dose of rosiglitazone is based on the previously published study (Zhao *et al*. 2012).

Body weight, feed intake and blood glucose (Accu-Check blood glucose monitor) were recorded weekly, except terminal blood glucose. A week before the sacrifice, rats were fasted overnight and undergone oral glucose tolerance test (OGTT) as previously described (Noto *et al*. 2006). At the end of the study, all rats were fasted overnight, asphyxiated with CO₂ and their blood and organs were collected. The blood samples were centrifuged at 2000 rpm for 10 minutes and the serum separated were stored at -80°C until further analyses. The thoracic aortas were isolated for vascular contractility studies.
**Serum biochemical analysis**

Terminal fasting blood samples were analysed for glucose (Cayman, 10009582, USA), total cholesterol (Cayman, 10007640, USA), total triglycerides (Zen-Bio, STG-1-NC, USA), high density lipoprotein (HDL) & LDL/vLDL (BioVision, K613-100, USA) and insulin levels (AlpcO Diagnostics, 80-INSRT-E01, USA) according to manufacturer’s instructions. The colorimetric and fluorimetric end points were measured in Varioskan Flash Multimode Reader (Thermo Scientific, USA).

**In vitro organ bath experiments**

This procedure was performed as previously described (Loong *et al*. 2015). Briefly, thoracic aortae were immediately excised and transferred into cold Krebs-Ringer bicarbonate solution upon sacrifice. In an aerated tissue bath, the aortic rings (4 mm) were left in the bath for 30-min to equilibrate before the application of 2g weight tension. Endothelium denuded rings were prepared by gently rubbing the intimal surface using the blunt tip of stainless steel forceps. Successful denudation was confirmed if the tissue produced less than 30% relaxation in the presence of 1x10^{-6}M carbachol in the pre-constricted rings. All aortic rings were pre-contracted to at least 70% of maximal contraction with 0.1 µM phenylephrine before the addition of isoprenaline (1x10^{-4} to 30 µM). Maximal relaxation \( R_{\text{max}} \) and pEC50 values were calculated using Prism version 6.0 (GraphPad Software, USA) in which EC50 is the concentration of isoprenaline that produces 50% of maximal relaxation and pEC50 is taken as the negative common logarithm of EC50.

**Calculations**

Weekly energy intake was calculated with the following formula:
Energy intake (KJ g\textsuperscript{−1})

\[ = \frac{\text{Metabolisable energy per gram of food (KJ g}^{-1}) \times \text{Average food consumed per rat (g)}}{\text{Average body weight per rat (g)}} \]

Homeostatic model assessment-insulin resistance (HOMA-IR) was calculated by taking the product of blood glucose in mg/dL and serum insulin in mU/L, divided by 405, as described previously (Mohankumar et al. 2012).

Lipoprotein ratios were obtained by using serum total, LDL and HDL cholesterol readings in mmol/L. Non-HDL cholesterol was calculated by subtracting HDL-cholesterol from total cholesterol. (Martirosyan et al. 2007) Ratios of LDL:HDL, total cholesterol (TC):HDL and non-HDL:HDL were obtained.

Statistics

Results are shown as means ± standard error of the mean for the number of rats tested. Statistical analyses were performed using unpaired Student’s t test to compare two groups and one-way ANOVA with Tukey’s post-hoc tests to compare three or more groups. Repeated measure one-way ANOVA was performed for concentration-responses and time responses. Analyses were done on SPSS version 22 (IBM, USA) and graphics prepared using Prism version 6.0 (GraphPad Software, USA). A probability of less than 0.05 (P<0.05) was considered to be statistically significant. Diet specific differences were compared with ND and treatment specific differences were compared with HFD.
RESULTS

Physical characteristics and Energy intake

First, we analyzed the effect of diet and treatment on body weight, organ weight and food intake. From week 4 onwards, all groups fed high fat diet (HFD, HFD+RGZ, HFD+CLA, HFD+RGZ+CLA) were ~20% heavier than normal diet (ND) (Figure 1A). Organ weights were similar in all groups except fat pads including epididymal, perirenal and mesenteric fats, the weight of groups fed high fat diet were 1.3 to 2.7 folds higher than normal diet (Table I). However, no treatment specific difference was observed (p > 0.05). Energy intakes, in kilojoules measured weekly, were similar across all groups (Figure 1B).

Blood glucose and insulin

Since hyperglycemia and insulin resistance are major hallmarks of T2DM and metabolic syndrome (Kaur 2014), we measured the fasting blood glucose and insulin levels to determine the effect of the diet and/or treatment of glycaemia.

The fasting blood glucose levels were found to be similar across all groups (Figure 2A). All rats were found to have similar glucose clearance with respect to OGTT (Figure 2B). In addition, whilst rats belonging to HFD+RGZ, HFD+CLA and HFD+CLA+RGZ groups geared towards improved insulin sensitivity as shown by homeostatic model assessment of insulin resistance (HOMA-IR) index (Figure 2C), they were not statistically different from ND or HFD control groups.

Serum lipoprotein levels and ratios

Atherogenic dyslipidemia is one of the critical metabolic characteristic of T2DM (Mooradian, 2009), hence various serum lipid markers of dyslipidemia were measured. As depicted in Figure 3A and 3D, neither diet nor treatments have altered the serum TC and triglyceride
levels. The serum LDL level was 46% reduced in HFD+CLA+RGZ group in comparison to HFD alone (p < 0.05, Figure 3B). Conversely, animals from HFD, HFD+RGZ and HFD+CLA have shown 1.3 folds elevated levels of HDL compared to ND (p < 0.05), whereas HFD+RGZ+CLA have 25% suppressed serum HDL than HFD group and the level was similar to the level measured in ND group (Figure 3C). A plethora of published studies reported that cholesterol ratios, especially LDL:HDL, TC:HDL and non-HDL:HDL ratios have been recognized as the critical markers of atherogenicity and are widely used to assess cardiovascular risk (van Deventer et al. 2011, Hermans et al. 2007, Lu et al. 2003). As shown in Figure 4A & 4B, the TC:HDL and non-HDL:HDL ratios in the animals received HFD or HFD+RGZ+CLA was 2-folds higher than ND (p < 0.05), whereas no significant changes observed for HFD+RGZ and HFD+CLA. Although the LDL:HDL ratio was lower in treatment groups (Figure 4C), they were not significantly different compared to ND and HFD, respectively (p > 0.05).

**Isoprenaline-induced vasorelaxation**

A set of preliminary experiments were conducted to optimize the experimental conditions for isoprenaline-induced relaxation (data not shown). Of note, the degree of initial contraction induced by 0.1 μM phenylephrine for both control and treatment groups either without or with endothelium were not statistically significant (P>0.05; data not shown). A representative trace of isoprenaline-induced relaxation in aortic rings excised from SD rats fed normal rodent chow diet is shown in Figure 5A.

The effect of diet and treatment on isoprenaline-induced vascular relaxation in isolated aortic rings excised from the rats was examined. The endothelial layer was removed on some of the aortic rings to check if the endothelium has been affected by the various treatments. All isolated aortic rings exhibited concentration-dependent vasodilatation in response to
isoprenaline as the vasodilator. Repeated measures analysis indicated that the isoprenaline-induced vasorelaxation was significantly different between ND, HFD and HFD+RGZ+CLA regardless of endothelial presence (Figure 5B & 5C).

Among endothelium intact rings (Figure 5B), all rings fed HFD, regardless of treatments were more responsive than ND. HFD+RGZ+CLA was the most responsive to isoprenaline. This was followed by HFD. The responsiveness of HFD+RGZ is intermediate of HFD and HFD+RGZ+CLA, while HFD+CLA is intermediate of HFD and ND. All groups exhibited similar pEC50 and Rmax (Table II and Figure 5B). However, the trend was reversed in endothelium denuded rings (Table II and Figure 5C). Removal of endothelium worsened the isoprenaline-induced vasorelaxation in all HFD and treatment groups. Of note, the relaxation was severely affected in aortic rings obtained from HFD+RGZ+CLA treated animals (pEC50=6 ±0.2, Rmax=53.6±4.7%) compared to ND (pEC50=7±0.2, Rmax=113±22%). Likewise, aortic rings from both HFD and HFD+CLA had diminished response to isoprenaline compared to ND (pEC50=6.6±0.1, Rmax=93±24.2% and pEC50=6.4±0.4, Rmax=77.70±22.8% respectively). Notably, the efficacy and potency of isoprenaline was significantly reduced in endothelium denuded aortic rings in comparison to endothelium intact aortic rings of HFD+RGZ+CLA treated rats (Endothelium intact: pEC50=7±0.2, Rmax=100±9.9% vs. endothelium denuded: pEC50=6±0.2, Rmax=53±4.7%) (Figure 5B & 5C), indicating the critical role of endothelium in protecting the PPAR agonists-mediated atherogenic risks.
DISCUSSION

Our key findings of this study were that the co-administration of CLA and rosiglitazone to SD rats fed HFD (60% energy from fat) had elevated TC: HDL and non HDL: HDL ratio, suppressed LDL and HDL level, and a marked decrease in endothelium-independent aortic relaxation, suggesting that CLA and rosiglitazone precede the atherogenic state and impaired endothelium-independent vasodilatation despite the onset of HFD-induced insulin resistance.

There have been previous efforts to examine feeding rosiglitazone and CLA alone in rodent models fed with HFD. Dietary supplementation with CLA for seven weeks, regardless of isomer composition, led to an improvement in glucose tolerance, insulin resistance and serum triglycerides (Choi et al. 2004). Likewise, treatment with rosiglitazone improved insulin sensitivity with a side effect of increasing serum LDL (Zhao et al. 2012). It is noteworthy that in this study SD rats were treated for four weeks to induce acute, instead of chronic effects as showed previously (Lessard et al. 2007, Murthy et al. 2005, Umrani et al. 2002). The onset of insulin resistance in animals can be influenced by a number of factors such as feeding period, type of fat in the diet and genotype of animals. We observed neither change in glucose tolerance nor obvious insulin resistance following 12 weeks of HFD. We reason that the rats used in our study possibly mimic the obesity resistant phenotype, since we did not observe significant impairments in glucose tolerance following HFD supplementation for 12 weeks, whilst rats gained marginal rise in body and fat pad weights compared to their normal diet counterparts (Dake and Oltman, 2015). Alternatively, as observed in earlier studies (Pranprawit et al. 2013, Stark et al. 2000, Xu et al. 2010), the period of less than 12 weeks is too short to induce metabolic changes in obesity resistant rats. In contrast, Huang and colleagues (Huang et al. 2004) reported reduction in glucose tolerance after 8 weeks of high
fat diet feeding. It is apparent that no standardization of diet induced obesity exists in literature despite using the common strain of SD rats. The studies that report the body weight reduction in SD rats with dietary supplementation of CLA, the animals have been fed with CLA from the beginning of the study together with HFD and report that CLA elicits isomer-specific effects (Choi et al. 2004). Conversely, in another study dietary supplementation of CLA mixture for 6 weeks in rats showed no change in body weight (Moya-Camarena et al. 1999). Thus, our observation that the absence of weight reduction following oral administration of CLA mixture (0.2gms/day) for 4 weeks in SD rats pre fed with HFD for 8 weeks could be explained by the duration of CLA supplementation and isomer composition of CLA mixture.

Dyslipidemia is linked to vascular dysfunction in T2DM (Dixon et al. 1999). Generally, increased circulating concentration of HDL is associated with lowered risk of cardiovascular disease. HDL are lipoprotein particles that mediate reverse cholesterol transport (RCT) with apolipoprotein A as the major protein component. Beyond its role in RCT, HDL binds to scavenger receptor (SR)-B1 and SR-B2 and directly exerts vasoprotective effects on the endothelium (Calabresi, 2003). Of note, as demonstrated previously by Tony Hayek et al., (Hayek et al. 1993) the increase in HDL is typical in rodents fed HFD. Thus, the HDL rise in our study is possibly an adaptive response to maintain vascular tone to compensate the increased atherogenicity brought by HFD.

CLA are known to be weak PPARα agonists (Moya-Camarena et al. 1999). While studies of rosiglitazone and CLA are difficult to come by, our observation of HDL reduction in HFD+CLA+RGZ treated rats is in agreement with the previous observations in case reports (Im et al. 2010, Normen et al. 2004, Schwing et al. 2010) and a clinical trial (Linz et al. 2014) in which rosiglitazone and fenofibrate, a commonly prescribed PPARα agonist, were simultaneously administered to human patients. Whilst the biological actions of CLA on
HDL and insulin sensitivity were complicated by isomer and composition dependence, our observation that a 1:1 mixture of c9,t11 and t10,c12-CLA increases HDL level is similar to a recent published study conducted in Wistar rats fed HFD (de Almeida et al. 2015). We have noted that HFD+RGZ+CLA brought about suppression of LDL and HDL without significant reduction in LDL:HDL ratio. Since fractions outside LDL and HDL are also involved in atherogenesis, we make use of the non-HDL:HDL ratio, also known as the atherogenic coefficient, that has been proposed to be better predictors of cardiovascular risks (Hermans et al. 2007, Kim et al. 2013). Another ratio, TC:HDL, is linked to non-HDL:HDL by a linear relationship. Both ratios were increased in HFD+RGZ+CLA group despite having similar HDL level with ND suggesting increased atherogenicity, that is corroborated with the decreased ability of aortic rings to respond to isoprenaline-mediated vasodilatation in HFD+RGZ+CLA treatment group.

It is well established that the changes in vascular function when fed an atherogenic diet precede the onset of insulin resistance and cardiovascular diseases. In agreement with these studies (Garcia-Prieto et al. 2015, Stark et al. 2000), we observed diminished endothelium-independent vasodilatation without significant changes in glycaemia. The vascular endothelium forms the inner lining of blood vessels and plays important role in maintaining vessel physiology (Deanfield et al. 2007, Hadi et al. 2005). Under physiological conditions, blood vessels are kept quiescent and dilated by endothelial secretion such as nitric oxide (NO). However, endothelial denudation due to apoptotic loss of endothelium is known to occur under the diabetic and insulin resistant state (Avogaro et al. 2011, Sena et al. 2013) The increased responsiveness in HFD-fed endothelium intact rings may be an acute adaptive response to high circulating lipoproteins. Similar observations were recorded in obese spontaneously hypertensive rats (Kagota et al. 2004).
Isoprenaline-induced vascular relaxation is dependent on β-adrenergic receptors present on both endothelium and vascular smooth muscle (VSM) (Akimoto et al. 2002). Endothelium-independent relaxation of VSM is mediated by NO produced in situ (Bernhardt et al. 1991). Our observation of vascular impairment in rosiglitazone fed endothelium denuded rings agrees with a previous finding, which stemmed from the improvement in endothelial production of NO but impaired response of VSM in rats (Onuta et al. 2008). The decreased responsiveness of endothelium denuded rings can be explained by rosiglitazone, via PPARγ, induced upregulation of CD36 in the VSM (Ballesteros et al. 2013, Kleinhenz et al. 2015), as CD36 is responsive to LDL and lead to inhibition of cGMP synthesis in the VSM (Isenberg et al. 2009). Conversely, it has been reported that t10,c12-CLA increases NO formation in human endothelium (DeClercq et al. 2012), nonetheless our observations warrant further studies to elucidate the precise mechanisms by which CLA modulate endothelium-independent relaxation.

The ability of aorta to constrict in obesity has been shown to be impaired due to many factors, including overnutrition of dietary fats (Stapleton et al. 2008). It has been previously reported that under certain environmental stressors, including HFD, the VSM cells tends to lose its contractile ability due to the remodeling of VSM into synthetic phenotype (Beamish et al. 2010). Stephanie et al. have demonstrated the impairments in phenylephrine-mediated contraction in aorta excised from SD rats fed HFD for 17 weeks (Stephanie et al. 2012). Conversely, we observed no differences with phenylephrine-induced contraction in both control and HFD diet groups. Whilst we reason that the differences could be due to the duration of HFD feeding, proportion of HFD and age of rats, the impairment in contractile ability of VSM in rodents fed HFD was shown prominent in small mesenteric arteries than the thoracic aorta (Soares et al. 2017).
In summary, while glucose tolerance and HOMA-IR may be unchanged, simultaneous administration of CLA and rosiglitazone led to increase in atherogenic coefficient. The increase in atherogenicity is coupled with vascular resistance in the context of endothelial loss. This observation hints the complex interplay between nutrient-drug interactions and warrants further investigation on their molecular mechanisms. Whilst it is believed that the use of normal rodent phenotype is limited in studying lipoprotein metabolism due to higher level of circulating HDL compared to humans, our observations, the linkage of cholesterol ratios and vascular resistance in SD rats fed HFD provides a reasonable basis for revisiting the lipoprotein dynamics in rodents.

ACKNOWLEDGEMENTS

We thank Ms. Ling Wei Chih for her help with animal care. We thank Ms. Akila Raghavan for analyzing blood glucose and total cholesterol. We would like to acknowledge the generous infrastructure provided by University of Nottingham Malaysia Campus (UNMC) and University of Malaya. This research was supported by UNMC Pump Priming grant and the Fundamental Research Grant Scheme from the Ministry of Higher Education, Malaysia (grant number: 64924).

Data were presented as mean ± SEM. * p < 0.05 compared to E+.
Figure 1. Effect of diet and treatments on body weight and energy intake. (A) Body weight of Sprague-Dawley rats throughout the study. (B) Average energy intake of Sprague-Dawley rats throughout the study. Data is presented as mean ± SEM, n=6 in all groups. # p < 0.05 compared to ND.
Figure 2. Effect of diet and treatment on glycaemia (A) Measurement of blood glucose level. Blood glucose on week 5 and week 8 measured using tail prick method; terminal blood glucose on week 13 measured using glucose assay kit. Data is presented as mean ± SEM, n=6 in all groups. (B) Oral glucose tolerance test (OGTT). A day before the 12 week, rats were fasted overnight before undergoing oral glucose tolerance test. (C) HOMA-IR of rats at termination. Data were presented as mean ± SEM, n=6 in all groups.
Figure 3. Effect of diet and treatments on lipid profiles. (A) Total cholesterol. (B) LDL-cholesterol. (C) HDL-cholesterol. (D) Triglycerides. Data were presented as mean ± SEM, n=6 in all groups. * p < 0.05 compared to ND. # p < 0.05 compared to HFD.
Figure 4. Effect of diet and treatments on lipoprotein ratios. (A) TC:HDL ratio. (B) non-HDL:HDL ratio. (C) LDL:HDL ratio. Data were presented as mean ± SEM, n=6 for each group. * p < 0.05 compared to ND.
Figure 5. Effect of diet and treatments on isoprenaline-induced aortic ring relaxation. (A) Representative trace of isoprenaline-induced aortic ring relaxation of normal SD rats. (B)
Relaxation of endothelium-intact aortic rings. (C) Relaxation of endothelium-denuded aortic rings. Data were presented as mean ± SEM, n=4-6 for endothelium intact and n=3 for endothelium denuded. For B and C, statistical significance is indicated by letters next to the legends, groups having the same letter(s) are not significant from each other.
