Abstract

Background. Arterial sites with low wall shear stress (WSS) are more prone to the development of atherosclerotic plaques, as was observed in carotid arteries in subjects with atherosclerosis risk factors. Type 2 Diabetes mellitus (DM), hypertension, hyperlipidemia and other components of the metabolic syndrome, are associated with high risk for symptomatic cerebrovascular disease. It was shown by others that untreated type 2 DM is associated with lower WSS in common carotid arteries. However, the cardiovascular risk of type 2 DM could be modified by therapy. The aim of our study was to test the hypothesis that treated type 2 diabetes mellitus (DM) subjects with metabolic syndrome still have lower WSS in common carotid arteries than healthy controls.

Methods. We enrolled 26 compensated DM subjects with metabolic syndrome, treated by metformin, statins and ACEI for more than 6 months, and 22 age-comparable healthy controls. Wall shear rate (WSR) was used as a measure of WSS. A linear 3-11 MHz probe was used to measure blood velocity and internal diameter in the common carotid arteries. We compared observed values of WSR adjusted for age by ANCOVA.

Results. Wall shear rate was significantly lower in DM group than in control subjects: peak (systolic) values of wall shear rate were $410 \pm 130 \text{ s}^{-1}$ vs. $487 \pm 111 \text{ s}^{-1}$, $p < 0.005$. DM subjects had significantly lower WSR, because of both thinner lumen and slower blood flow velocities. Lower WSR was accompanied by higher IMT ($0.73 \pm 0.12 \text{ mm}$ vs. $0.64 \pm 0.11 \text{ mm}$, $p < 0.001$)

Conclusions. Treated subjects with compensated DM with metabolic syndrome still have atherogenic hemodynamic profile. These findings might help to understand

faster progression of atherosclerosis in diabetic subjects with metabolic syndrome despite up-to-date medication.

Key words: ultrasonography, wall shear stress, wall shear rate, diabetes mellitus, carotid artery disease

Introduction

Atherosclerosis, the leading cause of death in the developed countries, is a consequence of both, the genetic predisposition and the traditional risk factors such as diabetes mellitus (DM) (Mayer-Davis 1998), hypertension (Berenson 1998), hyperlipidemia (Waters 1995), cigarette smoking (Howard 1998). Patients with type 2 DM are at high risk for cardiovascular disease (CVD); their risk is 2- to 6-fold higher than in subjects without diabetes (Kannel and McGee 1979; Stamler 1993).

Accelerated atherosclerosis in diabetic subjects is partially explained by the atherogenic risk factors associated with the metabolic syndrome (Alberti K. 2005).

Atherosclerosis is a systemic, multifactorial disease. Nonetheless, atherosclerosis remains a geometrically focal disease, preferentially affecting the outer edges of vessel bifurcations (Fox 1982). Local hemodynamic factors participate in the physiopathology of atherogenesis, accounting for the focal nature of the process (Asakura and Karino 1990). The main local hemodynamic factor is wall shear stress (WSS), the frictional force acting tangentially to the endothelial surface as a result of blood flow (Malek 1999). Wall shear stress is directly related to whole-blood viscosity and to wall shear rate (WSR) (Girerd 1996). Wall shear rate is defined as the difference between adjacent velocities in the vascular lumen. The ratio between the maximum velocity at the centre of the artery and vessel radius is a common approximation of WSS (Hoeks 1995). Wall shear rate can be used as an approximation of WSS (Hoeks 1995; Malek 1999). In the atherosclerosis-prone sites, blood flow is slow and changes its direction during the cardiac cycle, resulting in a low net hemodynamic shear stress. In contrast, vessel regions that are exposed to steady blood flow and a higher magnitude of shear stress remain comparatively plaque-free

e.g. flow-dividers in bifurcation (Zarins 1983; Gnasso 1997). Lower WSS induces rather larger lesions with vulnerable plaque phenotype, whereas vortices with oscillatory WSS induce stable lesions (Cheng 2006). Wall shear stress is not implicated only in vascular pathobiology, but also in vascular remodeling (Gibbons and Dzau 1994), and is a critical determinant of vessel caliber (Langille and O'Donnell 1986). The mechanisms, by which low WSS can cause arterial damage are known for a long time: the resultant stagnation of blood permits increased uptake of atherogenic blood particles as a result of increased residence time (Zarins 1983). Wall shear stress can change the morphology and orientation of endothelial cell layer (Malek 1999). Moreover, exposure of the arterial wall to a relatively low WSS may increase the vulnerability of these regions of the vessel to atherosclerosis (Malek 1999). Low WSS modulates the transcription of genes for nitric oxide, and increased local production of mitogenic substances (Traub and Berk 1998). This complex endothelial cell response to shear stress may also provide a mechanism by which known risk factors act to promote atherosclerosis.

Carotid atherosclerosis is also locally influenced by WSS. Irace et al. (Irace 1999) demonstrated that subjects suffering from carotid atherosclerosis, but with low calculated cardiovascular risk have lower WSS of the common carotid artery (CCA) than controls. Investigation on patients affected by unilateral carotid atherosclerosis demonstrated that shear stress is lower in the carotid arteries with plaques than in contralateral plaque-free arteries (Gnasso 1997). According to the study carried out by Irace et al. (Irace 1999) DM subjects have lower WSS of compared with age-matched healthy control subjects.

The high risk of CVD that accompanies metabolic syndrome and DM mandates comprehensive and complex preventive care. Drug therapy indicated for

cardiovascular risk reduction includes insulin sensitizers (metformin), angiotensin-converting-enzyme inhibitors (ACEI) (Yusuf 2000; Chitravas 2007) and lipid lowering therapy (statins) (Furberg 1994; Crouse 1995; Amarenco and Tonkin 2004). However, despite this medication diabetics have high risk of cardiovascular events. The aim of our study was to test the hypothesis that DM subjects with metabolic syndrome compensated by metformin, with established statin and ACEI therapy, still have lower WSR in the common carotid artery than healthy controls.

Methods

Diabetics with metabolic syndrome in accord with NCEP: ATP III criteria (Alberti K 2005), treated with metformin, statin and ACEI for more than 6 months were included into this study. All diabetics were overweight with central obesity (waist circumference above 102 cm in men and 88 cm in women). Diabetics were enrolled from the outpatient department, Third Department of Internal Medicine General University Hospital. We also examined healthy, age- and sex comparable subjects. Blood pressure (BP) was measured on the right arm, after 5 min rest, in a sitting position. Serum total cholesterol, triglycerides and HDL-cholesterol levels were measured using automated analyser methods; LDL-cholesterol concentrations were calculated using the Friedewald's formula, no participants had values of triglycerides above 4 mmol/l. Ultrasound examination was performed by the use of a linear-array 3-11 MHz probe of SONOS 5500 (Philips, Andover, Massachusetts, USA). The examinations were performed in fasting state (at least 12 hours) during morning hours. The subjects were kept in supine position with their heads slightly extended. We scanned CCA, carotid bifurcations and the origins of the internal carotid arteries in longitudinal and transverse planes. Subjects with stenosis of the carotid tree or

atherosclerotic plaque were excluded. Plaque was defined as a focal structure encroaching into the arterial lumen of at least 0.5 mm or 50% of the surrounding IMT value, or demonstrates a thickness >1.5 mm as measured from the media-adventitia interface to the intima-lumen interface (Meijer 2006). Ultrasound measurements were performed in CCA 1 to 2 cm proximal to the bifurcation. The distal segments of CCA were recorded digitally for further analysis. Blood flow velocity was detected with the sample volume placed in the center of CCA. Peak systolic (V_{peak}), end-diastolic (V_{min}), and mean velocities (V_{mean}) were recorded.

Both, the internal diameter (ID) and the common carotid intima-media thickness (CIMT) were analyzed off-line by specialized software Image Pro-Plus version 4.0 (Media Cybernetics, Silver Spring, Maryland, USA). The reader was the same throughout the study and was blinded with regard to the subject-investigated. CIMT, defined as the distance between two parallel lines: the lumen-intima and media-adventitia boundaries, was measured on the far wall of CCA and the average of three measurements was calculated. ID, defined as the distance between the leading edge of the echo produced by the intima-lumen interface of the near arterial wall and to the leading edge of the echo produced by the lumen-intima interface of the far wall, was measured on the top of the R-wave of QRS complex.

Wall shear rate was calculated using the Poiseuillian parabolic model of velocity distribution across the arterial lumen based on the assumption of laminar blood flow, according to the following formula (Gnasso 1996; Jiang 2000):

$$WSR_{peak} = 4 \times V_{peak} / ID$$

$$WSR_{mean} = 4 \times V_{mean} / ID,$$

where WSR is wall shear rate (s^{-1}), V is the velocity (cm. s^{-1}) and ID is the arterial diameter . Wall shear rate was calculated separately for peak and mean blood flow velocity.

Statistical analysis

Because the right and left sides were analyzed separately, analyses concerning carotid parameters were based on 52 samples in the diabetic group and 44 in the control subjects.

Statistical analysis was performed by Statistica for Windows ver.6.0 statistical software (StatSoft, In., Tulsa, Oklahoma, USA). Clinical differences between diabetics and controls were analysed using an unpaired *t*-test. Data are expressed as mean \pm SD. The analysis of co-variance (ANCOVA) was used to compare hemodynamic differences between age-adjusted DM subjects and controls. Univariate correlation analysis was performed to test possible influence of WSR and CIMT by age, ID, systolic blood pressure (SBP) and body mass index (BMI). Data is expressed as mean \pm SD and $p < 0.05$ was considered statistically significant.

Results

Table 1 shows clinical and biochemical characteristics of diabetics and that of controls. Diabetics had higher systolic blood pressure than healthy controls (137 ± 17 mmHg vs. 125 ± 20 mmHg, $p < 0.08$) despite being treated with ACEI. Subjects in both groups were overweight, but body mass index was significantly higher in diabetics (29 ± 3 vs. 26 ± 3 , $p < 0.001$). The total cholesterol (4.4 ± 0.9 mmol/l vs. 5.1 ± 0.8 mmol/l, $p < 0.001$) and LDL cholesterol (2.4 ± 0.6 mmol/l vs. 2.9 ± 0.7 mmol/l, $p < 0.001$) were lower in diabetics, as a result of statin treatment. HDL cholesterol was lower in DM

subjects (1.2 ± 0.2 mmol/l vs. 1.6 ± 0.4 mmol/l, $p < 0.001$) and the triglycerides were higher (1.8 ± 1.4 mmol/l vs. 1.4 ± 0.5 mmol/l, $p < 0.01$).

Hemodynamic parameters are listed in **Table 2**. Peak WSR was significantly lower in diabetics than in healthy controls (410 ± 130 s⁻¹ vs. 487 ± 111 s⁻¹, $p = 0.003$), because of both thinner lumen (6.7 ± 0.92 mm vs. 5.9 ± 0.64 mm, $p < 0.001$) and slower blood flow velocity (67.0 ± 16.7 cm. s⁻¹ vs. 71.4 ± 12.2 cm. s⁻¹, $p = 0.16$). Common carotid intima-media thickness was significantly lower in healthy controls (0.73 ± 0.12 mm vs. 0.64 ± 0.11 mm, $p < 0.001$). These results remained statistically significant even when adjusted also for systolic BP.

In diabetic group, significant correlation between peak wall shear rate and age ($r = -0.48$, $p < 0.0001$), mean wall shear rate and age ($r = -0.39$, $p = 0.004$).

Discussion

Our data demonstrate that treated diabetics with metabolic syndrome still have lower wall shear rate of the common carotid artery compared to healthy controls. These findings suggest that DM subjects with metabolic syndrome have a local carotid hemodynamic profile more prone to plaque development.

In our study, decrease of WSR was the consequence of both, lower blood flow velocity and enlargement of CCA. It was shown that the diameter of CCA increases with age (Eigenbrodt 2006). Our diabetics were slightly older than healthy controls, but we believe that this difference was not so high to explain different CCA diameters.

Moreover, we added age as a confounding factor to the analysis of covariance.

Eigenbrodt et al. reported that persons with pre-existing atherosclerotic disease or atherosclerotic risk factors have larger carotid diameters than persons without those attributes (Eigenbrodt 2006). This is thought to be an adaptive phenomenon (Safar

1998). Hypertension per se is a known variable associated with large internal and interadventitial diameter of CCA (Boutouyrie 1999). In the present study, we found a significant correlation between ID and SBP. Our results are in agreement with previous observations reporting relationship between ID and treated hypertension (Chironi 2003). The hypertension exerts a fatiguing effect on the elements of the arterial wall (i.e., elastin and collagen), resulting in degenerative changes and interadventitial enlargement. The role of DM in enlargement of CCA is not completely clarified. Henry et al. (Henry 2004) reported that DM is associated with a pattern of compensatory remodeling, i.e. preservation ID at increased CIMT. Diabetics in our study had dilated CCA, i.e. outward arterial remodeling (characterized by an increase in ID caused by a greater change in interadventitial diameter than in CIMT). This pattern of arterial remodeling of CCA appears maladaptive, and is associated with ischemic stroke independently of carotid atherosclerosis and cardiovascular risk factors (Bai 2007).

Decreased blood flow velocity in the CCA was reported in hypertensive subjects with left ventricular hypertrophy (Jiang 1998; Kohara 1999). Widening of pulse pressure in stiffer arteries was proposed as the mechanism of the alteration of blood flow velocity (Kohara 1999). Another possibility for explaining decreased blood flow velocity is an abnormality of cardiac function in DM subjects. Several studies demonstrated left ventricular diastolic dysfunction as a typical abnormality at early stage of DM, independent of the confounding role of myocardial ischemia, body weight, and BP (Celentano 1995; Di Bonito 1996).

In our study, CIMT was, as expected, higher in diabetic group than in healthy controls. One of the premises of CIMT is that it reflects atherosclerosis and cardiovascular risk. Atherosclerosis is restricted primarily to the intimal layer of the vessel wall. Ultrasound

imaging cannot discriminate between the intimal layer and the medial layer of the vessel wall. An increased CIMT may reflect either intimal thickening, thickening of the medial layer, or a combination of both. In the present study, we found a strong inverse correlation between WSR and CIMT in agreement with previous observations (Gnasso 1996) (Zarins 1983). We also found a significant influence of SBP and glycated hemoglobin on CIMT. Our results support the hypothesis of interactions between systemic and local risk factors able to influence atherogenesis. Association between glucose tolerance and CIMT was explained by hyperglycemia (fasting glucose or HbA1c) and/or insulinemia and insulin resistance (Wagenknecht 2003). Insulin in physiological concentrations stimulates the proliferation of smooth muscle cells and increases lipid activity and synthesis. High levels of glucose can damage or alter the endothelial barrier, thus allowing insulin to interact with the underlying smooth muscle cells. Systolic blood pressure is known to be associated with intima-media thickening (Vaudo 2000) and this finding was confirmed in our study. Linhart et al. (Linhart 1996) demonstrated that carotid artery structure may be representative of LV mass even when it is within normal limits.

Although WSR is a common approximation of WSS (Gnasso 1997; Irace 1999; Carallo 2006; Tuka 2006), the use of WSR might potentially lead to some inaccuracy. First limitation is that endothelial cells sense and respond to WSS, not WSR. Gnasso et al. (Gnasso 1996) measured blood viscosity in vitro by use of a cone/plane viscosimeter. It was shown that even actual measurements of viscosity must not lead to real values of shear stress (Setty 2002). Some authors (Zarins 1983; Paszkowiak 2003) use an arbitrary value for blood viscosity to estimate shear stress. The use of an arbitrary value of blood viscosity would not change the statistical significance of the results. For these reasons, we used WSR measurements.

Conclusion

This study has shown that treated subjects with compensated DM still have atherogenic hemodynamic profile. These findings might help to understand fast progression of atherosclerosis in diabetic subjects despite up-to-date medication.
